1. Field of the Invention

The present invention relates to a method of and apparatus for inspecting coins, and more particularly to a method of and apparatus for discriminating authenticity of coins, for use in automatic vending machines, game machines, etc.

2. Description of Related Art

An apparatus for inspecting coins, which is prevailing in recent years, is of an electronic type using induction coils.

This type of coin inspection apparatus generally utilizes the falling of coins due to their own weight and is provided with a passage for guiding a coin inserted from a coin slot. Also, a plurality of sets of induction coils are arranged along the passage to produce electromagnetic fields excited by respective different frequencies.

Inspection of coins is performed on the well-known principle. When a coin passes through the electromagnetic field, an amount of electrical change (change in frequency, voltage, or phase) derived due to the interaction between the electromagnetic field and the coin is detected to thereby inspect the authenticity of the coin.

Since in many cases features of coins appear in relation to frequency-dependent parameters, a conventional coin inspection apparatus employs techniques of inspecting materials, diameters, thicknesses, etc. of coins by using electromagnetic fields of a plurality of frequencies, as disclosed in U.S.

Patent No. 3,870,137.

In recent so-called borderless societies in which coins can be easily brought from one country to another, an increasing number of unacceptable coins tend to be used erroneously or deceitfully. Some of the coins used in various countries resemble each other in material, diameter, thickness, etc., and a typical example is 5-cent coin used in the U.S.A. and 5-centesimo coin used in Panama. Such coins differ from each other only in surface design (surface irregularity pattern) and are substantially identical with each other in material, diameter, and thickness. With the conventional arrangement using induction coils, a change in thickness caused by the surface irregularity pattern of coin cannot be detected by simply using a plurality of frequencies, with the result that resembling coins like those mentioned above cannot be discriminated from each other.

Attempts have also conventionally been made to adopt an optical process such as image processing as a means of discriminating resembling coins like those mentioned above. However, the optical apparatus has a problem in that the authenticity determination of coins can be adversely affected by adhesion of dust or the like, and also has a problem in that the apparatus is expensive because of its large size and complicated structure.

SUMMARY OF THE INVENTION

An object of the present invention is to provide a coin inspection method and an apparatus therefor capable of detecting a plurality of different parameters with a simple coil arrangement and discriminating coins of different materials and different surface patterns with high accuracy and low

cost.

In the coin inspection method of the present invention, an exciting coil and a receiving coil are arranged in the vicinity of one side of a coin passage so that the exciting coil and the receiving coil are electromagnetically coupled with each other, and the exciting coil is excited to oscillate at such a frequency that an influence of a reactive magnetic field produced by eddy current induced on a surface of a coin thrown into a machine when the coin passes through the electromagnetic field is detected by the receiving coil. Then, the authenticity of the thrown coin is discriminated based on at least one of amplitude, frequency and phase of the oscillation voltage of the exciting coil, and an electromotive force signal detected by the receiving coil.

The excitation frequency is preset in accordance with material of the coin to be inspected. The material of the thrown coin can be determined based on the amplitude of the oscillation voltage of the exciting coil, and a feature of surface irregularity pattern of the thrown coin can be determined based on the electromotive force signal from the receiving coil. Thereby, the coin is inspected by the authenticity discrimination based on the material of the coin and the authenticity discrimination based on the feature of surface irregularity pattern of the coin.

The coin inspection apparatus of the present invention for carrying out the above-described method comprises an exciting coil arranged in the vicinity of one side of a coin passage; a receiving coil arranged in the vicinity of the one side of the coin passage so as to be electromagnetically coupled with the exciting coil; oscillation means for exciting and oscillating the exciting coil at a predetermined frequency to produce an electromagnetic field ; first detecting means for detecting at least one of amplitude, frequency and phase of the

oscillation voltage of the exciting coil; second detecting means for detecting an electromotive force signal generated in the receiving coil; and discriminating means for discriminating authenticity of the thrown coin based on detection outputs from the first and second detecting means.

Further, the coil arrangement may be such that an exciting coil is arranged in the vicinity of one side of a coin passage inclined at a predetermined angle so that magnetic poles thereof face the coin passage, and two receiving coils having substantially identical characteristics are arranged in the vicinity of the one side of the coin passage so that the receiving coils are electromagnetically coupled with the exciting coil.

BRIEF DESCRIPTION OF THE DRAWINGS

FIGS. 1a and 1b are a front view and a sectional view, respectively, showing a detection coil arrangement according to an embodiment of the present invention;

FIG. 2 is a block diagram showing a circuitry arrangement for a coin inspection apparatus according to the embodiment of the present invention;

FIG. 3 is a diagram showing details of the circuitry shown in FIG. 2;

FIG. 4 is a front view showing the outline of the coin inspection apparatus;

FIG. 5a is a front view showing the details of an exciting coil shown in FIGS. 1a and 1b, and FIG. 5b is a sectional view showing the details of a receiving coil;

FIG. 6a is a graph showing an oscillation voltage waveform detected by the exciting coil, and FIG. 6b is a graph showing a waveform obtained by

rectifying the waveform shown in FIG. 6a;

FIG. 7 is a characteristic diagram showing features of irregularity patterns of representative coins;

FIG. 8 is a table showing comparison of data of the representative coins;

FIG. 9 is a flowchart of inspection processing to be performed by an MPU of a control unit;

FIGS. 10a and 10b are a front view and a sectional view, respectively, showing another detection coil arrangement;

FIGS. 11a and 11b are a front view and a sectional view, respectively, showing still another detection coil arrangement;

FIGS. 12a and 12b are a front view and a sectional view, respectively, showing still another detection coil arrangement; and

FIG. 13 is a schematic view for showing a structure in which a material of high magnetic permeability is used for a portion of a coin passage wall at which receiving coils are arranged.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

FIGS. 1a and 1b show an arrangement of detection coils for detecting a material and a surface irregularity pattern of a coin, and FIG. 2 shows a circuitry arrangement for a coin inspection apparatus.

Referring to FIGS. 1a and 1b, the detection coils consist of one exciting coil 1 and two receiving coils 2a and 2b, and are arranged along a passage wall 7a on one side of a coin passage 6. The coin passage 6 is sloped at a predetermined angle to allow a coin 3 to roll down while being guided

thereby, and comprises a coin rail 4 arranged at the bottom thereof and a pair of passage walls 7a and 7b. The passage walls 7a and 7b are, as shown in FIG. 1b, inclined with respect to the vertical direction so that the coin 3 may roll down while being inclined toward the passage wall 7a. Also, the surface of the coin rail 4, on which the coin is guided, is inclined in the direction in which the passage walls 7a and 7b are inclined so that the coin 3 passing thereon may be inclined toward the passage wall 7a.

Each of the two receiving coils 2a and 2b comprises, as shown in FIG. 5b, a drum type core 43 and a winding 44 wound around the core 43. As shown in FIG. 1a, the receiving coils 2a and 2b are arranged above the coin rail 4 at a predetermined distance from each other so that a line 5a connecting the centers of the coils 2a and 2b is substantially parallel with the coin rail 4.

The exciting coil 1 comprises, as shown in FIG. 5a, a U-shaped core 40 made of a magnetic material and a winding 41 wound around the core 40. As shown in FIG. 1a, the exciting coil 1 is arranged above the receiving coils 2a and 2b so that the center C3 of the core 40 thereof is located on a line 5c which is perpendicular to the line 5a connecting the centers C1 and C2 of the receiving coils 2a and 2b and which passes through the middle point M of the line segment C1C2 and also that a line 5b connecting the centers of two pole faces 40a thereof is substantially parallel with the coin rail 4. Further, as shown in FIG. 1b, the core 40 is arranged so that the pole faces 40a thereof are parallel with the face of the coin 3 passing thereby. In FIGS. 5a and 3b, reference numerals 42 and 45 each denote a lead wire.

The exciting coil 1 and the receiving coils 2a and 2b arranged as described above are electromagnetically coupled by means of an electromagnetic field produced by excitation of the exciting coil 1.

Referring to FIG. 2, reference numeral 11 denotes an oscillation circuit. The oscillation circuit 11 comprises a resonance circuit made up of an exciting coil 1, a capacitor C1, and a capacitor C2 and a feedback circuit 12 connected to the resonance circuit. The oscillation circuit 11 oscillates at an oscillation frequency based on the resonance frequency of the resonance circuit to produce an oscillation voltage at both ends of the exciting coil 1, by which the exciting coil 1 is excited. Thereby, the exciting coil 1 generates an electromagnetic field around the exciting coil 1. The oscillation circuit 11 outputs the oscillation voltage produced at both ends of the exciting coil 1 to a first detector circuit 13a. The first detector circuit 13a, which is supplied with the oscillation voltage from the oscillation circuit 11, outputs a direct voltage signal corresponding to the oscillation voltage to an inspection means 16. When the coin 3 is located near the exciting coil 1, an eddy current is generated within the coin, so that a magnetic flux in the exciting coil 1 is hindered by a reactive magnetic field, as described later, produced by the eddy current, leading to a change in the amplitude, frequency and phase of the aforementioned oscillation voltage at both ends of the exciting coil 1. This change differs depending on the material of coin. Thereby, when the coin 3 moves in the vicinity of the exciting coil 1 and is acted upon, the oscillation voltage serves as a signal mainly representing the feature of material of the coin 3. Therefore, by inspecting this signal, the feature of material of coin to be discriminated can be inspected.

In the two receiving coils 2a and 2b constructed as described above, on the other hand, an electromotive force corresponding to the strength of the electromagnetic field produced by the exciting coil 1 is generated. As described above, the exciting coil 1 and the receiving coils 2a and 2b are

preferably arranged so as to be close to the face of the coin 3 to carry out inspection.

When the coin 3 is acted upon by the electromagnetic field formed as described above, eddy current is induced in the vicinity of the surface of the coin 3 excited by the exciting coil 1, and with an increase in excitation frequency, the eddy current is generated intensely in the vicinity of the outer periphery of the coin due to skin effect.

When the coin 3, which is a conductor, moves in the magnetic field produced by the excitation coil 1, an inductive electromotive force is generated and the eddy current as the induced current flows on the surface of the coin 3. According to Lenz's law, the eddy current as the induced current flows in the direction such that a magnetic field produced by the induction current prevents the change of the magnetic flux produced by the excitation coil 1. In the following description, the magnetic field produced by the induced current is referred to as a "reactive magnetic field".

Thus, the eddy current produces the reactive magnetic field in the vicinity of the outer periphery of the coin and the reactive magnetic field interacts with the receiving coils 2a and 2b according to a subtle change of the contour feature of the coin surface. In each of the receiving coils 2a and 2b, produced is an electromotive force corresponding to such a change of the reactive magnetic field indicative of the contour feature of the coin 3. A signal generated by the electromotive force is hereinafter referred to as a "detection signal".

Further, since the magnetic poles of the exciting coil 1 are arranged in the vicinity of the receiving coils 2a and 2b, a change of the reactive magnetic field produced when the coin 3 acts on the electromagnetic field produced by

these magnetic poles can be acquired at a location near the magnetic poles.

The reactive magnetic field produced due to the skin effect is noticeably observed near the outer periphery of the coin, but in cases where coins have large surface irregularity, the region of coins where a change of the reactive magnetic field can be detected is not particularly limited to the outer peripheral region alone. Based on the detection signal of the receiving coils 2a and 2b, a corresponding alternating voltage signal is generated in a bridge circuit 14 including the receiving coils 2a and 2b, and is output to an differential amplifier circuit 15. The differential amplifier circuit 15 amplifies the alternating voltage signal generated by the bridge circuit 14, and outputs the amplified signal to a second detector circuit 13b. The second detector circuit 13b, which is supplied with the alternating voltage signal amplified by the differential amplifier circuit 15, outputs a direct voltage signal corresponding to the detection signal to the inspection means 16. The inspection means 16 supplies the direct voltage signal to an AD converter 17 provided therein, and the AD converter 17 converts the direct voltage signal into a digital signal of a corresponding voltage. The digital signal is output to a signal inspection circuit 18 provided in the inspection means 16. The signal inspection circuit 18 determines whether or not the coin 3 has a given feature, and outputs the result of determination to an output terminal 19. The output of the signal inspection circuit 18 is used to drive a deflector solenoid 35, described later, or a coin counter or the like, not shown.

FIG. 3 is a diagram specifically showing the details of the block circuits shown in FIG. 2. FIG. 4 shows the coin inspection apparatus, and FIG. 5 shows a coin arrangement.

Referring to FIG. 3, the arrangement of the individual circuits shown in

the block diagram of FIG. 2 will be described in detail. The oscillation circuit 11 comprises the resonance circuit constituted by the exciting coil 1, capacitor C1, and capacitor C2 and the feedback circuit 12 constituted by a comparator C01, feedback resistor R3, and resistor R4.

The first detector circuit 13a comprises a rectifier circuit (voltage multiplying rectifier circuit) including diodes D1 and D2 connected to a coupling capacitor C7 connected to the output of the oscillation circuit 11, and an integrating circuit including a resistor R9 and a capacitor C9.

The bridge circuit 14 comprises a capacitor C3 connected in parallel with the receiving coil 2a (inductance L2), a capacitor C4 connected in parallel with the receiving coil 2b (inductance L3), and resistors R1 and R2.

The differential amplifier circuit 15 comprises capacitors C5 and C6 connected to the output of the bridge circuit 14 in an AC coupling fashion, an operational amplifier A1, and resistors R5, R7 and R6, R8 connected so as to determine the gain of the operational amplifier A1.

The second detector circuit 13b comprises a rectifier circuit (voltage multiplying rectifier circuit) including diodes D3 and D4 connected to a coupling capacitor C8 connected to the output of the differential amplifier circuit 15, and an integrating circuit including a resistor R10 and a capacitor C10.

The AD converter 17 and the signal inspection circuit 18 of the inspection means 16 are constituted by using an MPU (microprocessor unit).

The oscillation circuit 11 excites the exciting coil 1 with a predetermined frequency. The frequency is preferably one at which the electromagnetic field does not penetrate into the coin, being preferably in the range of 70 kHz to 90 kHz. An experiment according to the present invention

pattern of the coin was produced by eddy current induced on the coin surface and was detected as a subtle difference in electromotive force generated in the aforementioned two receiving coils. The above difference could not be detected by conventional techniques.

Referring now to FIGS. 4 and 2, the operation of an apparatus 30 for determining authenticity of coins will be described in detail.

In the authenticity determination apparatus 30 for coins shown in FIG. 4, a coin 3 inserted from a coin slot 31 falls naturally due to its own weight onto the coin rail 4 arranged under the coin slot 31. The coin 3 thus dropped on the coin rail 4 rolls down through the coin passage 6 (FIG. 1b) in a downstream direction away from the coin slot 31. While moving through the coin passage 6, the coin 3 passes by a diameter detection coil 32 and a material/irregularity detection coil including the exciting coil 1 and the receiving coils 2a and 2b. The apparatus 30 determines the authenticity of the coin 3 while the coin 3 passes by the individual detection coils. If, as a result of the determination, the coin 3 is judged to be genuine, a deflector solenoid 34 is driven in accordance with the signal output to the output terminal 19, to actuate a gate 33 so that the coin 3 is guided to a genuine-coin passage, not shown. On the other hand, if as a result of the determination the coin 3 is judged to be a false coin, the gate 33 is not actuated, so that the coin 3 is guided to a false-coin passage, not shown, to be let out from an outlet, not shown.

When the coin 3 is genuine and thus introduced to the genuine-coin passage, it continues to fall naturally and drops onto a coin rail 35. The coin 3 which has dropped onto the coin rail 35 is then sorted by conventionally known sorting means, not shown, according to denomination, and let out from

obtained by sampling the DC voltage output from the first detector circuit 13a, and is stored in the memory. Further, from the data obtained by sampling the DC voltage output from the second detector circuit 13b and the statistic of the acceptable coin stored beforehand in the memory 21, the computation in the aforementioned equation (1) is performed to obtain a correlation coefficient r , and the obtained correlation coefficient r is stored.

In the authenticity determination process of Step 105, it is judged whether or not the minimum value of output of the first detector circuit 13a determined by the computation process in Step 103 falls within a preset reference range. If the value falls within the reference range, it is judged that the material is identical with that of the acceptable coin, and if the value does not fall within the reference range, it is judged that the material is different from that of the acceptable coin. Thus, the material of coin is determined. Also, the correlation coefficient r obtained by the computation process of Step 103 is compared with the predetermined value of acceptable coin stored in advance, whereby the irregularity pattern of the coin 3 is determined.

If the material of coin in question is judged to be identical with that of the acceptable coin, and if the relationship, correlation coefficient $r >$ predetermined value, is fulfilled, the coin in question is judged to be genuine, and the program proceeds to a genuine-coin process in Step 106. On the other hand, if the material of coin in question is judged to be different from that of the acceptable coin, or if it is judged that the relationship, correlation coefficient $r <$ predetermined value, is fulfilled, the coin in question is judged to be false; in which case the program executes a false-coin process in Step 104 and returns to the standby loop.

An alternative method may be used in which the authenticity

determination process based on the material of coin is first carried out, and if the material of coin in question is judged to be different from that of the acceptable coin, the computation process for determining a correlation coefficient r for determining the irregularity pattern and the authenticity determination process by means of the correlation coefficient r are not carried out. Specifically, a minimum value is determined from the data obtained by sampling the DC voltage output from the first detector circuit 13a, and it is judged whether or not the minimum value falls within a preset reference range, to determine the material of the coin 3. If the value does not fall within the reference range, it is judged that the material of the coin 3 is different from that of the acceptable coin, the program proceeds to Step 104 without executing the computation process and judgment for determining the irregularity pattern of the coin 3 and without carrying out the authenticity determination. In Step 104, the false-coin process is executed. Only when the minimum value of sampling data falls within the reference range, and the material of coin in question is judged to be identical with that of the acceptable coin, a correlation coefficient r is obtained to determine the irregularity pattern of the coin 3.

When the coin in question is judged to be genuine in the authenticity determination process of Step 105, the genuine-coin process is executed in Step 106. In the genuine-coin process of Step 106, a process of outputting a genuine-coin signal, a denomination signal, etc. is executed in accordance with the result of authenticity determination, whereupon the program returns to the standby loop.

Although the exciting coil 1 using a \sqsupset -shaped core is shown in the above-described embodiment, another shape such as a U shape may be used

appropriately without departing from the spirit and scope of the present invention.

The arrangement of the exciting coil 1 and the receiving coils 2a and 2b of the detection coil for detecting the material and irregularity of coin is not limited to that of the above-described embodiment, and the arrangement may be changed according to the shape, surface pattern, etc. of the coin to be discriminated.

As shown in FIGS. 10a and 10b, the exciting coil 1 and the receiving coils 2a and 2b may be arranged so that the line 5b connecting the centers of the pole faces 40a at the longitudinally opposite end portions of the \sqcap -shaped core 40 of the exciting coil 1 is perpendicular to the line 5a connecting the centers of the receiving coils 2a and 2b and passes through the middle point M between the centers C1 and C2 of the receiving coils 2a and 2b. The operation and effects of this arrangement are identical with those of the above-described embodiment, and therefore, the description thereof is omitted.

As shown in FIGS. 11a and 11b, the line 5a connecting the centers of the receiving coils 2a and 2b may be shifted in the vertical direction with respect to the coin rail 4 on which the coin 3 rolls down, so as to pass through the central position of the coin 3 to be detected. In this case, the receiving coils 2a and 2b are arranged at a location corresponding to the central position of the coin 3 to be detected, and accordingly, the detection value varies in accordance with a difference in surface irregularity pattern of the central portion of the coin 3, so that the arrangement is suited for judging the authenticity of coins by determining whether or not the coin has a hole in the center thereof.

Further, as shown in FIGS. 12a and 12b, the side-by-side arrangement

of the receiving coils may be rotated by 90 degrees so that the line 5a connecting the centers of the receiving coils 2a and 2b may be perpendicular to the line 5b connecting the centers of the pole faces of the core of the exciting coil 1 and pass through the center of the exciting coil 1. Also in this case, the receiving coils 2a and 2b are arranged at a location corresponding to the central position of the coin to be detected, and therefore, this arrangement is suited for judging authenticity of coins by discriminating between presence and absence of change in the surface irregularity pattern of the central portion thereof.

As described above, the position where the receiving coils 2a and 2b are arranged (the position where the exciting coil is arranged in relation to the position of the receiving coils) may be changed in accordance with a difference in surface irregularity pattern of coins whose authenticity is to be determined (depending on whether the difference in surface irregularity pattern exists in the central portion, e.g. presence/absence of a hole, or in the peripheral portion of the coin).

Also, according to the present invention, the exciting coil 1 is excited at a frequency such that the electromagnetic field produced penetrates only into the surface region of the coin but not up to the central region of the same, and the influence of a reactive magnetic field caused by eddy current induced in the vicinity of the surface of the coin is measured. Accordingly, the surfaces of the receiving coils 2a and 2b facing the coin should desirably be as close to the coin surface as possible. As shown in FIG. 13, therefore, a portion of the passage wall 7a where the receiving coils 2a and 2b are arranged, that is, a portion of the passage wall 7a extending along the line 5a connecting the centers of the receiving coils 2a and 2b as shown in FIG. 1a, may be made of a

material 200 having high magnetic permeability, so that the receiving coils 2a and 2b may be virtually located closer to the surface of the coin.

According to the present invention, since the material and surface irregularity pattern of coin can be detected by the use of a set of simple coils, it is possible to provide at a low cost a small-sized, high-performance coin inspection apparatus capable of dealing with a diversity of coins.
